TECHNICAL MEMORANDUM

SIGNIFICANT EVENTS IN LOW-LEVEL FLOW CONDITIONS HAZARDOUS TO AIRCRAFT

INTRODUCTION

Diverse requirements exist for information describing phenomena in the lowest 150 m of the Earth's atmosphere. Particular needs are related to conditions hazardous to the ascent and descent of conventional aircraft and Space Shuttle. But, relatively little high-resolution data from aircraft and/or meteorological towers are available to determine and describe the magnitude, frequency, duration, and simultaneity of occurrence of low-level flow conditions in the vicinity of runways.

Conditions known to be hazardous to aircraft during takeoff/climbout and approach/landing operations are turbulence, wind shear, and vertical motion. Turbulence produces rapid aircraft oscillations such as shaking, pitching, and yawing. Wind shear is a wind change producing an increase or decrease in air speed. Vertical motion, updrafts and downdrafts, produces an increase or decrease in altitude. Wind shear in a zone between relatively calm wind in a temperature inversion and strong horizontal wind above the inversion can cause an abrupt turbulence encounter at low altitude.

All these conditions can and frequently do occur simultaneously. This study was initiated to determine actual occurrences and values for these conditions during strong or gusty surface winds near a runway.

LOW-LEVEL FLOW CONDITIONS

Turbulence, wind shear, and vertical motion effects in terminal operations are all, separately and in combination, serious problems in aviation safety.

Turbulence

A turbulent atmosphere is one in which air currents vary greatly over short distances. These currents range from mild eddies to strong currents. An aircraft moving through these currents undergoes changing accelerations or turbulence [1]. This condition ranges from annoying bumpiness to damaging jolts.

Two measures of turbulence near the Earth are gustiness and gust factor. Gustiness, the difference between maximum and minimum wind speeds during an interval, is reported at one airport if it exceeds 13 ms⁻¹ (25 knots) at any level [2]. The dimensionless gust factor represents a maximum wind speed fluctuation about a mean speed during an interval. For operational problems at Kennedy Space Center, Florida, the environmental criteria value for gust factor over a 10-min averaging period for mean wind speed varies with peak speed and height, i.e., for high wind speeds (> 10 ms⁻¹) the gust factor varies from 1.7 at 10 m to 1.3 at 150 m [3].

It should be noted that gustiness and gust factor in the literature usually refer to horizontal wind speed. This study includes horizontal wind speed and direction as well as vertical motion.

Wind Shear

The meteorological mechanisms that cause strong wind shears are gust fronts formed by severe thunderstorms, fast-moving frontal zones, and low-level temperature inversions [4]. Wind shear generates eddies between two wind currents of differing velocities. The differences may be in wind speed, wind direction, or in both.

Wind shear may be associated with a wind speed gradient or a wind shift at any level in the atmosphere. Wind speed shears greater than 0.1 s⁻¹ in the lowest 100 m are known to be dangerous to large, swept-wing, jet-powered aircraft [5] while large changes in wind direction (>40 deg) are considered hazardous [6].

Wind shear with a low-level temperature inversion can cause an aircraft to abruptly encounter turbulence with a loss of airspeed and possible stall. Temperature normally decreases with increasing altitude throughout the troposphere. This decrease of temperature with altitude is defined as lapse rate. The average lapse rate is 2°C per 300 m. But, temperature sometimes increases with height through a layer. An increase with altitude is defined as an inversion and may occur near the ground-surface inversion — or at any altitude — an inversion aloft. At the Helsinki-Vantaa Aerodome pilots are warned of temperature increases >10°C between any level and the surface [2].

Vertical Motion

The simultaneous occurrence of vertical motion (updrafts and downdrafts) and shear can cause serious problems for approaching and departing aircraft at airports. Describing statistical properties of these occurrences facilitates accuracy in model simulations during adverse conditions. Snyder [5] simulated an aircraft on final approach and subjected it to the events of sudden shear, downdraft, and airspeed drop. Using Snyder's analog computer study and a simple flow model, Kalafus [6] achieved results consistent with Snyder's: that a 0.08 s⁻¹ shear is a typical one associated with a 2.57 ms⁻¹ downdraft and that a 0.17 s⁻¹ shear is a reasonable one for a 5.15 ms⁻¹ downdraft. Alexander and Campbell [7] concluded that models for simulating aircraft ascent and descent under adverse conditions should show simultaneously occurring downdrafts and shears to be independent and uncorrelated.

DATA ACQUISITION AND ANALYSIS

The NASA 150-Meter Ground Winds Tower Facility at Kennedy Space Center, Florida, is a unique source of high resolution wind and temperature profile measurements. The 150-m and 18-m towers, depicted in Figure 1 and described by Kaufman and Keene [8], are located on Merritt Island midway between Launch Complex 39B and the Space Shuttle runway. Placement of the meteorological sensors on the towers is shown in Figure 2. The Automatic Data Acquisition System, described by Traver, et al. [9], samples at the rate of 10 each of speeds, directions, and temperatures per second, digitally records, and real-time processes the samples for all sensors on the two towers.

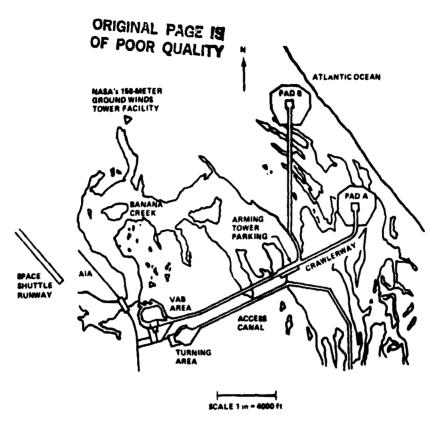

Figure 1. NASA's 150-Meter Ground Winds Tower Facility and Launch Complex 39, Kennedy Space Center, Florida.

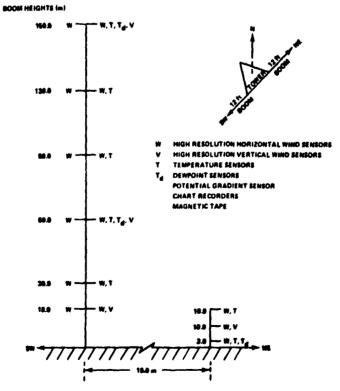

Figure 2. Placement of Sensors on NASA's 150-Meter Ground Winds Tower Facility at Kennedy Space Center, Florida.

This analysis consists of six 5-sec intervals (one interval every 100 sec) from 2143 47.0 to 2152 16.9 UT on July 3, 1973, during high (10 < 18 ms⁻¹) to gale-force (18 < 33 ms⁻¹) horizontal winds recorded at eight tower heights with associated vertical motion and temperature differences. Associated parameters are defined as those sampled and recorded simultaneously with horizontal wind speed and direction. This analysis is concerned with the WMO-recommended practices [10], viz., that wind-averaging periods for aviation climatology not exceed 10 min, gust-measuring periods be at least 5 sec, and temperature measurements be at 1.25 to 2 m above ground level.

The significant events emphasized in this study of six 5-sec intervals (2143 47.0-51.9, 2145 27.0-31.9, 2147 7.0-11.9, 2148 47.0-51.9, 2150 32.0-36.9, and 2152 12.0-16.9) include the following:

- 1) Horizontal wind speed and direction gustiness and gust factors for eight heights: 150, 120, 90, 60, 30, 18T¹, 18S¹, and 3 m.
- 2) Vertical wind speed (updrafts and downdrafts) gustiness and gust factors for four heights: 150, 60, 18T and 10 m.
- 3) Wind speed shear >0.1 s⁻¹ and wind direction shear >1.0 deg m⁻¹ for six vertical layers: 150-120, 120-90, 90-60, 60-30, 30-18T, and 18S-3 m; and one horizontal distance: 18T-18S m.
 - 4) Updrafts and downdrafts ≥1.0 ms⁻¹ for four heights: 150, 60, 18T and 10 m.
 - 5) Positive temperature differences for six layers: 150-3, 120-3, 90-3, 60-3, 30-3, and 18S-3 m. Gustiness is defined to be

$$G = WS_{max} - WS_{min} \quad , \tag{1}$$

where WS_{max} is the wind speed maximum in a 5-sec interval and $WS_{n \cdot in}$ is the minimum value.

Gust factor is

$$GF = WS_{max}/\overline{WS} \quad , \tag{2}$$

where WS is the mean speed for an interval.

Wind direction gustiness and gust factor are similarly determined, i.e.,

$$G = WD_{max} - WD_{min}$$
, ORIGINAL PAGE IS OF POOR QUALITY

$$GF \approx WD_{max}/\overline{WD}$$
 (4)

1. 18T and 18S denote the 18-m level on the tall and short towers, respectively.

Vertical wind shear is the change of wind speed with height and is determined by means of two anemometers mounted at different heights on a single tower. Vertical shear magnitudes were derived by algebraically subtracting the wind speed at the lower level from the speed at the upper and dividing by the distance between levels, i.e.,

$$\frac{WS_U - WS_L}{d_{(U-L)}} = \frac{\Delta WS}{\Delta d}$$
OF POOR QUALITY. (5)

Horizontal wind shear is the change of wind speed with horizontal distance and is determined by two anemometers mounted at the same height on different towers. Wind speed shears for one distance (18 m) between the tall and short towers at the 18-m level are presented. Horizontal shear magnitudes were derived by algebraically subtracting the wind speed at the short tower from the speed at the tall and dividing by the distance between towers, i.e.,

$$\frac{WS_T - WS_S}{d_{(T-S)}} = \frac{\Delta WS}{18} \qquad (6)$$

Vertical and horizontal wind direction shears were similarly determined, i.e.,

$$\frac{WD_{U} - WD_{L}}{d_{(U-L)}} = \frac{\Delta WD}{\Delta d} \quad . \tag{7}$$

and

$$\frac{WD_T - WD_S}{d_{(T-S)}} = \frac{\Delta WD}{18} \quad . \tag{8}$$

RESULTS

Tabular presentations of the magnitude, frequency, and duration of the significant events by height, layer, and/or distance during strong or gusty surface winds are as follows:

- 1) Tables 1 through 6 list magnitude, frequency, and duration of significant events for six 5-sec intervals from 2143 to 2152 UT.
- 2) Table 7 lists extreme values, total frequencies, and maximum continuous durations of significant events for the approximately 10-min data period.

Graphical depictions of the simultaneity of occurrence of significant events for each 0.1 sec of six 5-sec intervals are as follows:

- 1) Figures 3, 6, 9, 12, 15, and 18 are plots of the occurrences of significant events b, heights and layers.
- 2) Figures 4, 7, 10, 13, 16, and 19 are tallies of the simultaneous occurrence of significant events in combination.
- 3) Figures 5, 8, 11, 14, 17, and 20 are tallies of the simultaneous occurrence of separated significant events.

Four portrayals for each 5-sec interval illustrate the hazardous low-level flow conditions, e.g., Interval 2143 47.0-51.9 UT: Table 1 and Figures 3, 4, and 5; Interval 2145 27.0-31.9 UT: Table ? and Figures 6, 7, and 8, etc. Table 1 includes actual values (max, min, mean, and std. dev.), frequencies, and continuous durations of significant events. Figure 3 depicts the occurrence of significant events per tower height, shear layer/distance, and temperature layer. Figures 4 and 5 present a tally of the simultaneous occurrence of the combined and separated, respectively, significant events (maximum horizontal wind speeds and directions, wind speed shears $\geq 0.1 \text{ s}^{-1}$, wind direction shears $\geq 1.0 \text{ deg m}^{-1}$, updrafts and downdrafts $\geq 1.0 \text{ ms}^{-1}$, and positive delta temperatures emphasized in this period of strong or gusty surface winds.

CONCLUSIONS

Regarding magnitude, frequency, duration, and simultaneity of occurrence of significant events during high ($10 < 18 \text{ ms}^{-1}$) and gale-force ($18 < 33 \text{ ms}^{-1}$) winds for six 5-sec intervals within a 10-min period:

- 1) The maximum horizontal wind speed and direction (used to determine gustiness and gust tactor as measures of turbulence near the surface) occurred simultaneously infrequently at 3 or more heights and persisted <0.4 sec.
- 2) Wind speed and direction gustiness and gust factor values increase with decreasing height, i.e., wind speed gustiness of 3.8 ms⁻¹ at 150 m to 6.8 ms⁻¹ at 3 m and gust factor of 1.083 at 150 m to 1.674 at 3 m, wind direction gustiness of 14 deg at 150 m to 76 deg at 3 m and gust factor of 1.029 at 150 m to 1.226 at 3 m.
- 3) Vertical wind speed and direction shears increase with decreasing height, persist continuously from 3 to 5 sec and occur simultaneously in four and five layers below 90 m.
- 4) Occurrence of vertical motion is approximately equal of 1200 measurements 614 were updrafts and 586 were downdrafts with updrafts ≥ 1.0 ms⁻¹ exceeding downdrafts ≥ 1.0 ms⁻¹ by approximately 50 percent (160 to 88).
- 5) Temperature inversions occurred in layers below 90 m and persisted continuously for 5 sec for five of the six intervals in the lowest layer (18S-3).

6) Total frequency of occurrence of significant events ranged from 4 to 14 events per 0.1 sec and from 360 to 520 per 5.0 sec.

This study certainly lends support to the ideas that information on low-level flow conditions hazardous to aircraft is most important over the lowest 150 m of the Earth's atmosphere and that similar analyses during high vertical motion and strong low-level temperature inversion with associated parameters should be made for information, comparison and flight simulation purposes.

APPROVAL

SIGNIFICANT EVENTS IN LOW-LEVEL FLOW CONDITIONS HAZARDOUS TO AIRCRAFT

By Margaret B. Alexander and Dennis W. Camp

The information in this report has been reviewed for security classification. Review of any information concerning Department of Defense or nuclear energy activities or programs has been made by the MSFC Security Classification Officer. This report, in its entirety, has been determined to be unclassified.
